A new method of calculation of the lattice energy of binary ionic crystals of MX type was developed [1]. It enabled to deduce a new universal formula for the lattice energy calculation taking into account only ion radii values without introducing any additional arbitrary factors. It is pointed out that the exactness of $U_{i_a}t$ calculation depends upon the ionnity bond degree [1].

The above-mentioned allowed deducting an equation for *a priori* calculation of the length of interatomic distances in crystals and gaseous molecules assuming that all the bonds are of pure ionic type [2].

Furthermore, the equation for the calculation of ion radii with an arbitrary effective charge was deduced [3J.

Subsequent transformation of the received expressions allowed to obtain the equation for *a priori* calculation of melting point of crystalline alkaline metals halides . This equation is based an the magnitudes of ionic radii , bond ionnity degree, masses and principal quantum numbers of elements, i.e. $T_{me}it = f(Ri , £l2 , m. , n,)$. The error of calculation of $T_{me}it$ makes -2,4%.
